## Abstract

We review current and new estimates of the eclipsing binary YZ Casiopeiae metallicity ( $Z$ ). Since the individual components cover a quite large range of mass ( $1.35\text{--}2.31M_{\odot}$ ), YZ Cas is potentially one of the best stellar laboratories to understand the structure and evolution of 1 to 2  $M_{\odot}$  stars. The derivation of  $Z$  from IUE spectra, as well as from photometric indices, provides the chemical composition of the atmosphere ( $Z_{\text{atmospheric}}$ ), while the fit of evolutionary tracks provides the initial chemical composition ( $Z_{\text{initial}}$ ). While a disagreement is expected between  $Z_{\text{atmospheric}}$  and  $Z_{\text{initial}}$  because the primary component is an Am star (one expects  $Z_{\text{atmospheric}}$  to be larger), we find some unexpected discrepancy between atmospheric determinations of  $Z$  for this star.

## 1. $Z_{\text{ATMOSPHERIC}}$ FROM IUE SPECTRA

From IUE spectra of the YZ Cas primary, [LM83] found that the metals add up to a  $Z$  value of over 0.03 ( $Z=0.036\pm0.005$ ). We try to assess to what extent this high  $Z$ -value has to be revised. It is well known that the abundance of iron is enhanced in Am stars with respect to normal A-F stars. [LM83] found for YZ Cas A that Fe is  $\sim 6$  times

overabundant, which implies that Fe contributes to  $\sim 43\%$  of Z. In order to update the [LM83] study, we applied two corrections to this value: 1) They assumed an iron solar abundance  $A_{Fe}=7.60$ . More detailed studies give  $A_{Fe} = 7.50 \pm 0.05$  ([GS99]) implying that Fe contributes to  $\sim 57\%$  of Z. 2) Their analysis assumed  $T_{\text{eff}}=10,300\text{K}$ . Recent determinations give  $9100 \pm 300\text{K}$  ([R00]). This would reduce the [LM83]'s iron abundance by about 0.15-0.20 dex, and then imply that Fe contributes to  $\sim 33\%$  of Z. Both corrections are opposite and imply altogether that Fe contributes to  $\sim 40\%$  of Z. Hence, our attempt to update some of the [LM83] assumptions does not change their high-Z conclusion.

## 2. $Z_{\text{ATMOSPHERIC}}$ FROM PHOTOMETRIC CALIBRATIONS

Since *uvby* $\beta$  Strömgren colours are available for both components of YZ Cas ([L81], [J97]), it is possible to derive [Fe/H] from existing calibrations. The [J97] photometric indices do not suggest a metallic behaviour of the Am star atmosphere: [Fe/H] is  $-0.02 \pm 0.22$  ([J00]), i.e.  $Z = 0.017^{+0.012}_{-0.007}$  (assuming  $Z_{\odot}=0.018$ ). The upper limit is only marginally compatible with the Z derived from the IUE spectra. Assuming the individual photometric indices from [L81], the derived atmospheric [Fe/H] is  $0.12 \pm 0.05$ , i.e.  $Z = 0.024 \pm 0.003$ , again only marginally compatible with the IUE determination. Using Strömgren photometry from [J97] and accurate gravities, [L99] derived simultaneous  $T_{\text{eff}}$ -[Fe/H] estimates from the BaSeL photometric calibrations ([L98]). They obtain [Fe/H] strictly lower than 0.1 for YZ Cas A, i.e.  $Z < 0.022$ . This result assumes no reddening which is justified by experiments we performed with the BaSeL models (see [L99] for details on the method) for  $E(b-y)$  ranging from  $-0.034$  (*negative* value of [L81]) to 0.09 (maximum value quoted by [LM83]). In summary, even if the results of [J00] and [L99] are not completely independent because based on the same colour indices, they suggest that the atmospheric metallicity of YZ Cas A is solar or sub-solar, and exclude Z-values greater than 0.03.
